Upgraded Software and Embedded Improvements: A Puzzle of User Heterogeneity.

Raviv Murciano-Goroff, Ran Zhuo, and Shane Greenstein April 2024

PRELIMINARY. PLEASE DO NOT QUOTE. COMMENTS WELCOME.

Abstract

How prevalent are severe software vulnerabilities, how fast do software users respond to the availability of secure versions, and what determines the variance in the installation distribution? Using the largest dataset ever assembled on user updates, tracking software server updates by over 150,000 medium and large U.S. organizations between 2000 and 2018, this study finds widespread usage of server software with known vulnerabilities, with 57% of organizations using software with severe security vulnerabilities even when secure versions were available. The study estimates several different reduced-form models to examine which organization characteristics correlate with higher vulnerability prevalence and which update characteristics causally explain higher responsiveness to the releases of secure versions. The disclosure of severe vulnerability fixes in software updates does not jolt all firms into installing them. Factors related to the cost of updating, such as whether the software is hosted on a cloud-based platform and whether the update is an incremental change or a major overhaul, play an important role. Observables cannot easily explain much variation. These findings alter how firms' relative (in)attentiveness to act on software update releases should be incorporated into the design of cybersecurity policies.

Murciano-Goroff: ravivmg@bu.edu, Boston University; Ran Zhuo: ranzhuo@umich.edu, University of Michigan; Greenstein: sgreenstein@hbs.edu, Harvard Business School and NBER. We are grateful to Kenji Nagahashi and Mark Graham from The Internet Archive for providing the data for this research and appreciate the feedback we received from Sam Ransbotham, Ashish Arora, Ivan Png, Min Jung Kim, and seminar participants at the University of Toronto, University of Illinois, Purdue, Wharton, and Harvard Business School. We also thank Harvard Business School and the Ewing Marion Kauffman Foundation for funding this work. The authors are pleased to acknowledge that the computational work reported in this paper was performed on the Shared Computing Cluster, which Boston University's Research Computing Services administers. We have used ChatGPT to proofread and make stylistic improvements to the passage. The authors take responsibility for all errors.

1. Introduction

Over the past twenty years, disruptive cyberattacks on companies have increased (EY Americas, 2021). Many cyberattacks exploit vulnerabilities in the software running on companies' servers, even when the software vendors previously acknowledged the vulnerabilities and provided updates to fix them (Ranger, 2019). For example, in 2017, the UK's National Health Service fell victim to a cyberattack that exploited a vulnerability in their server software. A software update had been available to fix that vulnerability for over a month, but it had not been installed (Acronis International, 2017; Palmer, 2017). The cyberattack resulted in the cancellation of thousands of operations, including those of emergency patients. In the same year, hackers exploited a vulnerability in the server software hosting the Equifax website, exposing the information of over 143 million individuals (Goodin, 2017). Once again, a patch had been available for two months. In 2018, the city of Atlanta suffered a hacking incident, halting many of the city's departments and operations. Following the incident, an audit found 1,500 to 2,000 vulnerabilities in the city's system, with some of the vulnerabilities being present for almost a year (Harvey, 2018; Goldenberg and Zlatev, 2022).

These events garnered media attention and spurred calls from policymakers for increased investment and diligence in cybersecurity (Barrett, 2018). The policy proposals considered in the wake of these incidents took different forms. Some policies encouraged vendors to produce higher-quality software by making software vendors liable for the cost that users face from installing patches (August and Tunca, 2011).² Researchers also encouraged vendors to release updates and patches more quickly by mandating the public disclosure of security vulnerabilities (Arora, Telang, and Xu, 2008). Other proposals suggested restricting the frequency of software update releases and the amount of information software vendors disclose about vulnerabilities, decreasing the potential for malicious actors to learn from the vulnerability disclosures (Rescorla, 2004; Mitra and Ransbotham, 2015).

Whether or not these policies are beneficial depends on three related factors: untested assumptions about the *prevalence* of security vulnerabilities in installed and actively used server

-

¹ Other examples include Bank of America's ATMs being out of service and Continental Airlines' flight being cancelled due to cyberattacks exploiting unpatched vulnerabilities over six months old (Baroudi Bloor, 2003).

² August and Tunca (2011) study the provisioning of patches in an environment with profit-maximizing software vendors. In our study setting, the software is open-source and created by a group of volunteers and a non-profit foundation. Thus, charging the "software vendor" for patch costs is impossible.

software, the *determinants* of firm decisions regarding whether to install software updates for server software with vulnerabilities and the *responsiveness* of firms to attributes of the updates released, such as whether they respond faster to an especially severe vulnerability. These factors are consequential. *Prevalence* matters because mandating disclosure of vulnerabilities may decrease (increase) malicious attacks if users largely follow (ignore) mandates to install updates. The *determinants* of vulnerabilities in software firms matter because if they positively (negatively) correlate with the sensitivity of data and the related value of installing security software updates, then a policy of taxing (subsidizing) software usage could dissuade (encourage) firms with poor (good) updating practices from using vulnerable software. Finally, suppose firms adopt routines that respond to (ignore) information about the severity of risks. In that case, disclosing such information may speed up (have no effect on) user patching and reduce (increase) cybersecurity risks.

There is little empirical evidence on any of these three factors. That gap reflects the challenges of collecting and analyzing data about company software updating decisions over time and across different circumstances. Previous research relied on anecdotal narratives from small cross-sections of firms, but such data does not fully inform the discussion. For example, annual surveys (e.g., Harte Hanks) lack information on the precise timing of update installations, or retrospective reports (e.g., that consulting report we read) describe firms that have experienced hacking incidents but do not paint a picture of all firms. Indeed, to our knowledge, no data set provides information on software updates' prevalence, determinants, and responsiveness across a broad spectrum of firms and over an extended period.

This study addresses this gap by analyzing detailed panel data that tracks web server software. Web server software offers a valuable lens on this gap in research for several reasons. Web servers are ubiquitous and critical to the modern web-based commercial Internet. Millions of firms in the United States and hundreds of millions across the globe use web servers to support billions of web pages, including those serving sensitive financial and personal information (Greenstein and Nagle, 2014). Therefore, highlighting the prevalence of vulnerabilities and the instigators of installing updates can improve understanding of cybersecurity. Besides the cybersecurity benefits, many server software updates include features and bug fixes that improve the experience of Internet users. Therefore, increasing the speed at

which companies respond to software updates could also support productivity improvements and enhance the user experience.

The analysis focuses on organizations using the Apache web server, the most popular web server software deployed globally in the first few decades of the commercial Internet. In addition to its widespread use by millions of businesses, Apache is ideal for study because it publishes detailed information about its versions, updates, and vulnerabilities. Our data include the websites of over 150,000 U.S. medium to large companies and organizations using the Apache web server between 2000 and 2018. During this period, 28 severe vulnerabilities and 130 less severe vulnerabilities were discovered in the Apache software. Each vulnerability reported to Apache was scored along multiple dimensions. In addition, during the same time period, 115 software updates for the Apache server software were released, along with a list of the security vulnerabilities being corrected, the bugs fixed, and the new features included in the updates. Apache is open source, and each update was made freely available to anyone online without restrictions on who could use it or how it could be used. That also has advantages for empirical analysis of the timing of installing these software updates, which is not confounded by the changes in the pricing of the software or the policies regarding the availability of updates. Hence, the study treats the discovery of security vulnerabilities as a quasi-natural experiment in user updating that enables the estimation of several different reduced-form causal models.

Using this data, we were able to document the prevalence of security vulnerabilities in the server software actively used by companies to host their websites, examine the determinants of firm decisions regarding whether to install software updates and identify the features of released server software updates associated with faster adoption by firms.

The measurement of updates comes from raw data recorded on the Internet Archive's Wayback Machine, which has routinely visited millions of websites monthly and recorded the content and metadata about that site, including the name and version number of the server software hosting each website. By tracking the server software used to host each organization's website over time, it is possible to observe when an organization updates its server software or when an organization chooses to forgo updating and instead use the aging or vulnerable software. This paper's dataset is the largest assembled about user installations of software updates. Section 4 explains how the dataset is compiled after Sections 2 and 3 review relevant theory and background.

The analysis proceeds along three related lines. First, Section 5 assesses the prevalence of security vulnerabilities in the server software of organizations using Apache and finds widespread use of server software with severe security vulnerabilities. Between 2000 and 2018, nearly 76% of the firms analyzed postponed software updates for severe security vulnerabilities for at least six months. Almost every Apache webserver hosting the organization's homepages has operated with a publicly disclosed severe security vulnerability in some months. In other months, less than 25% contained one or more severe vulnerabilities. While the precise configuration of companies' server systems may prevent some of these vulnerabilities from being exploited by malicious actors, this finding suggests that a surprisingly large number of firms operate their websites using relatively outdated and potentially insecure server software.

Second, Section 6 analyzes the determinants of firm decisions regarding whether to install software updates. Linear probability and Poisson analysis of the number of vulnerabilities show that factors related to the cost of updating, such as whether a company hosts their server on a cloud provider, can explain more of the variation than factors associated with the value of cybersecurity, such as having a high-traffic website or monetization on the site. In contrast, firms that stand to lose the most from a cyberattack, such as high-traffic websites and organizations whose websites have monetization technologies, are surprisingly more likely to have vulnerabilities in their software.

After the econometric specification controls for various organizational characteristics, few observables can account for the lion's share of variation in organizations' responses to released software updates. For example, an organization's industry, geography, and website characteristics do not strongly predict its routine regarding whether to allow vulnerabilities to accumulate or install updates promptly. Instead, persistent unobservable differences between organizations drive varying update rates.

Section 7 explores the responsiveness of firms to attributes of the updates released, such as whether they respond faster to an especially severe vulnerability. It documents the characteristics of organizations and attributes of the Apache software updates associated with the faster or slower installation of those updates in the presence of newly discovered severe vulnerabilities. The best-fitting hazard model with time-varying covariates is a stratified hazard specification, which accounts for persistent unobservable differences between organizations. The estimates from this model show that organizations are faster at installing minor updates or updates that exclusively fix security vulnerabilities. They are slower to install multifaceted and complex updates.

The final section of this article, Section 8, discusses the policy and managerial implications of the findings. Since most firms are predominantly inattentive to vulnerability disclosures, releasing software updates with less information about the vulnerabilities inside may be socially efficient. Furthermore, the estimates imply that firms should pay more attention to how technical complexity can inhibit them from staying secure. Automating updating, such as services provided through the cloud, could help speed up updating.

This examination fills a critical empirical gap in the cybersecurity literature. While previous theories analyzing potential cybersecurity policies made differing prescriptions depending on software users' behavior, much of the prior literature about cybersecurity and software updates focused on software vendors (Arora, Nandkumar, and Telang, 2006; Arora, Telang, and Xu, 2008; August and Tunca, 2011; Mookerjee et al., 2011; Mitra and Ransbotham, 2015). With few exceptions, most of these papers portray software users' decisions regarding when to install updates as deterministic or a function of update quality (Arora, Telang, and Xu 2008). No empirical evidence verifies these behavioral assumptions.

Previous work has acknowledged that not all firms immediately install patches after their release. However, these findings are based on limited descriptions of user-updating behavior from the selected firms. For example, Arbaugh et al. (2000) examined data on the vulnerabilities exploited by hacked firms. Still, they lacked data on the fraction of firms operating with known vulnerabilities that did not get hacked. Empirically, this study fills this gap by documenting the prevalence of firms using server software with vulnerabilities over nearly two decades.³

This study also contributes by explaining the factors influencing the rate at which firms install software updates. Like the framework presented by Dey et al. (2015), this study's approach builds on the long-noticed phenomenon of considerable heterogeneity in the regular updating cycle and firms' approaches to installing software updates (Arbaugh, Fithen, and McHugh, 2000). Some companies routinely update their server software, while others have a more ad-hoc approach to updating. In addition, among companies that wish to eventually adopt software updates, a variety of frictions and costs can cause delays in installing those updates (Baroudi Bloor, 2003; Dissanayake et al., 2022; August and Tunca, 2006; August et al., 2014;

³ This includes the number of new features, bug fixes, severe and non-severe vulnerabilities fixed in each update.

Kang, 2022).⁴ This approach to empirical modeling and analysis enables inference as to why some firms keep their server software close to the technological frontier and install available updates promptly, while in contrast, others seem to plod along, accumulating vulnerabilities.

In addition, this study answers a long-standing call for understanding the factors influencing firms' responsiveness to the release of software updates. In their research on the tradeoffs of mandating faster disclosure of software vulnerabilities, Arora, Nandkumar, and Telang (2006) acknowledge the possibility that releasing a patch could increase the number of cyberattacks and called for empirically understanding the factors that hasten or slow user-patching as a promising area for future research. This study leverages the quasi-random discovery of vulnerabilities to analyze longitudinal data to gain causal inferences on the factors impacting update decisions. This gives us insights into the attributes of a firm and software that influence server updating.

Only two prior empirical research studies have examined longitudinal investment in cybersecurity and linked it to outcomes. Li et al. (2021) examined hospital adoption of security software and investment in related activities, while Liu et al. (2020) examined higher education and governance and associated actions. Both papers link these security investments to the propensity to suffer a security incident and exogenous organizational features and processes, using cross-sectional variance to infer causal determinants. Unlike these, the data used in this analysis allows us to see the precise time each firm installed each software update released between 2001 and 2019. This level of detail enables us to estimate both firms' routine rate of updating and the time-varying factors that increase or decrease the updating rate.

-

⁴ Kang (2022) emphasizes user incentives for upgrading enterprise software with many complements and the costs of accounting for such operational complexity. In a for-profit setting, August et al. 2014 investigate optimal trade-offs between the cloud-supported provision of upgrades or on-premises upgrades in the face of heterogeneous user valuation of quality. For-profit firms target their promotions to segments that demand low, medium, or high security, depending on the risks and costs of alternatives. Relatedly, August and Tunca, 2006 analyze incentives to patch in both a for-profit and free setting if upgrade behavior reflects forward-looking incentives but ignores externalities on others. In the for-profit environment, incentives to fix are too low, requiring vendor subsidies to induce optimal behavior. With freeware, the incentives are too low (high) when the risks and costs are minor (significant).

⁵ Li (2021) stresses the returns at organizations that invest in on-premises processes, such as anti-virus, intrusion detection, and authentication. Liu (2020) found behavior consistent with a tradeoff between granting autonomy and flexibility in using information systems and enforcing standardized, organization-wide security protocols—the more complex the computing environment, the higher the returns on centralized governance that limits vulnerabilities.

2. Theory of Server Software Users' Response to Software Updates

The prevalence of users operating software with known vulnerabilities, the determinants of firm decisions regarding whether to install software updates and the responsiveness of users to the release of updates that fix vulnerabilities are consequential factors for evaluating cybersecurity policies. This section provides a sketch of why these three factors impact the effectiveness of policies regarding cyber security proposed in the literature and motivates this study's empirical investigations of them.⁶

Prevalence. The prevalence of firms operating with known security vulnerabilities in their existing operations influences whether cybersecurity policies based on mandated disclosure of security vulnerabilities are, on average, beneficial or detrimental. Arora, Caulkins, and Telang (2006) recommend that policymakers mandate that software vendors disclose known vulnerabilities within a relatively short time to motivate those vendors to produce and release updates quickly.

However, the benefits of disclosure must be weighed against the detrimental effects. On the one hand, mandated disclosure provides malicious actors information that could be useful for hacking systems that have yet to install the updates to fix associated vulnerabilities. If most firms install updates when vulnerabilities are disclosed, then mandated disclosure will increase the provisioning of updates and improve the security of firm software. On the other hand, if most firms forgo installing available updates, policymakers need to be cautious with such a policy. Therefore, the prevalence of known vulnerabilities is a crucial empirical primitive to document and analyze.

Determinants. Why does a population of software users display different prevalences of vulnerabilities within their installed software? The determinants of firm decisions regarding whether to install software updates play an essential role in policy recommendations.

⁶ While the models of firm software users vary somewhat across papers in the literature, most have a similar setup.

attack, the probability of the attack may be proportional to the fraction of other firms who also do not patch. In addition, the expected damage from an attack may be proportional to the firm's value from its system.

Typically, these models represent firms' decisions regarding installing a security update as a static problem. Firms have idiosyncratic values when using a particular piece of software. When a patch is released, firms that install the patch pay a fixed cost of patching but gain protection from the associated security vulnerability. In contrast, firms that do not patch face the expected cost of a hack of their systems (the probability of a hack scaled by the expected damage). For vulnerabilities with negative externalities, such as when a hacked system may be used in a DDOS

August and Tunca (2006) suggest several mechanisms to improve user incentives to install updates and patch vulnerabilities, including patching rebates and taxing software users to dissuade low-valuation firms who are not reliable patchers to abandon the software rather than use the software without installing software updates. The optimality of those mechanisms depends on both the cost of patching and the value risked by not patching. For example, for freeware, August and Tunca (2006) conclude that a usage tax is the most effective policy except when both patching costs and value at risk are low, in which case a patching rebate prevails.

By similar reasoning, mandating disclosure of software vulnerabilities will hasten the provision of those updates and secure sensitive information if firms from industries with particularly sensitive data, such as finance and health firms, typically install available updates to patch vulnerabilities in their systems. If, on the other hand, firms with sensitive data are slower at installing software updates – perhaps because they have more rigorous update processes – then mandated disclosure may be detrimental specifically to those with the most sensitive data. Therefore, understanding the correlations between firm attributes and the prevalence of vulnerabilities is essential for evaluating which cybersecurity policies are welfare-improving.

Responsiveness. The preceding concern directs attention to explaining why some firms tolerate more vulnerabilities than others. A related issue focuses on understanding why firms respond more promptly to specific software updates than others and what factors influence this variability. Responsiveness is a critical element of many models used to evaluate cybersecurity policy.

Mitra and Ransbotham (2015) assess the optimal amount of information software vendors should disclose in updates. This decision involves a trade-off. On one hand, providing information about vulnerabilities gives malicious actors information that could be used to attack systems. On the other hand, providing information about vulnerabilities may also instigate more firms to install updates and patches if the details about the vulnerability frighten the firms regarding the risks of not installing the associated updates. Moreover, disclosing information about new functionalities and features in software updates, in addition to vulnerability fixes, could either signal significant costs related to installation or the additional value of updating. Whether providing detailed information about vulnerabilities or new functionalities will be beneficial depends on whether detailed information and what kind of information induces firms to install updates.

Rather than relying on assumptions about the prevalence of vulnerabilities, their determinants, and the responsiveness of update releases, this study leverages granular data to investigate and quantify these crucial parameters.

3. Setting

This study focuses empirical analysis on the Apache HTTP Server software (hereafter referred to as "Apache") and the organization that supports it, the Apache Software Foundation (ASF). Four reasons motivate this focus. First, as the second most popular open-source project after Linux, Apache represents a significant component of the digital economy. Second, the ASF's processes for reporting, disclosing, and rectifying security vulnerabilities reflect the security practices typical of open-source software. Third, potentially severe and economically significant consequences could result from poorly secured Apache server software, so the setting has policy importance. Lastly, the setting enables the collection of highly detailed data on Apache usage, vulnerability status, and updating behavior for a large group of U.S. firms, enabling empirical analysis.

Server software like Apache is a computer program that enables users to host a website. When an individual visits an organization's website, the individual's web browser sends a request to that organization's server. The server processes the request using server software that determines which content to send back to the individual. For example, after an individual connects to Amazon.com, the Amazon server software determines which products and prices to display to that individual. Similarly, after an individual connects to their bank's website and accesses their online banking accounts, the server software transmits the individual's login information and other sensitive personal financial data between the individual's web browser and the bank.

Apache's emergence as a popular server software, tracing back to the early days of the digital revolution, makes it ideal for studies in open-source software and cybersecurity. Apache descended from the first server software. In 1993, the National Center for Supercomputing Applications (NCSA) at the University of Illinois developed a computer program called the NCSA HTTPd server, which supported sharing content on the newly diffusing World Wide Web. NCSA made HTTPd available as shareware within academic and research settings, along with the underlying code. HTTPd's adoption spread quickly, partly because the servers did not

restrict the usage or modification of the software. Many web administrators took advantage by adding improvements as needed. In 1995, different teams of developers decided to coordinate their efforts into one server known as Apache (ostensibly because it was "a patchy web server"). The University of Illinois then transferred the development to the ASF without licensing or restrictions. Apache subsequently became popular as the commercial internet grew and became widely used. Murciano-Goroff, Zhuo, and Greenstein (2021) found that Apache was the most popular server software and powered 40% of the websites of medium to large U.S. firms between 2000 and 2018.

Today, the ASF coordinates the development of the Apache server software, receives reports of vulnerabilities, orchestrates the disclosure of vulnerabilities, and releases software updates to mitigate those vulnerabilities. Their vulnerability handling process has been typical of open-source software.⁷

In the most standard scenario, the ASF accepts reports from users about potential vulnerabilities. A team of security experts vet these submissions, known as *reported vulnerabilities*. After evaluating a reported vulnerability, the ASF initially keeps the reported vulnerability secret from the public so malicious actors are kept from being tipped off about its existence. At the same time, teams of developers develop a fix. When the ASF believes it is prudent to do so, it publicly discloses the vulnerability. We refer to these as *disclosed vulnerabilities*. The ASF discloses these vulnerabilities when it is essential to warn their users about security risks to encourage them to monitor their systems more carefully or to take mitigating actions, such as updating their software. When a fix for the vulnerability is successfully developed, the ASF releases the fix as part of a new version of Apache. At that point, Apache users decide whether and when to update their software to the latest version, and the vulnerabilities are called *fixed vulnerabilities*. To decrease the probability that malicious actors exploit a vulnerability, the ASF often releases the software update and discloses the vulnerability simultaneously.

While this is the process that the ASF hopes will occur, some vulnerabilities are discovered and handled outside this procedure. Some vulnerabilities are discovered when a user

⁷ The statement of this process is available on the Apache Software Foundation Security Team website at https://www.apache.org/security/. To the best of our knowledge, the overview of this process has stayed the same since the early days of the Apache Software Foundation.

notices and discusses problems with the program without knowing the situation, indicating an underlying vulnerability. In those cases, the date the vulnerability is reported and the date the ASF publicly discloses the vulnerability may be the same, and the ASF may disclose the vulnerability before a software update with the fix is ready to be released.

Hundreds of Apache vulnerabilities reported, disclosed, and fixed have severe consequences. Using data feeds provided by the ASF, the National Institute of Standards and Technology (NIST) scores vulnerabilities based on their potential to harm users. We call vulnerabilities "severe" when the vulnerabilities score "high" for severity in the scoring system. These severe vulnerabilities are particularly harmful for two reasons. First, these vulnerabilities are easily exploitable. According to the scoring system, most severe security vulnerabilities do not require local access to the system to perform the attack; attackers can perform the attack over the network and often need no or little authentication to access and exploit the vulnerability. Moreover, once exploited, these vulnerabilities can result in significant losses. These include and are not limited to a partial or total disclosure of user information, modifying some or all the files in a system, reduced performance, or a complete system shutdown (Mell et al., 2007). As of August 1, 2018, among the 158 Apache vulnerabilities reported, 28 vulnerabilities scored "high" in severity.

Beyond Apache's widespread use, its representative process for managing vulnerabilities, and its cybersecurity policy significance, the context is enriched by the availability of detailed data on Apache usage and update practices among a broad array of U.S. organizations. Furthermore, the ASF has made public extensive information on each Apache version's vulnerabilities, fixes, and feature enhancements, enabling precise measurement of users' vulnerability and fix status. These data aspects will be elaborated on in the following section.

.

⁸ The ASF submits Apache vulnerabilities to the Common Vulnerabilities and Exposures (CVE), an international, community-based data registry for cybersecurity vulnerabilities. Using CVE's data feed, the NIST maintains the National Vulnerabilities Database (NVD). When a vulnerability is reported to CVE, it is entered in the NVD, and a score is computed based on the Common Vulnerability Scoring System (CVSS). https://nvd.nist.gov/vuln-metrics/cvss#

4. Data

This section explains the essential and ancillary data sources. A summary of data sources is presented in Table 1. We defer the construction of our various samples to their respective sections later.

4.1. Key data source – server software usage panel of U.S. organizations

The critical data source is a broad panel data set that tracks server software used by medium to large organizations in the U.S. between 2000 and 2018. It records the usage of Apache and other server software, including Microsoft's IIS and Nginx, and tracks the installation of updates over time.

This panel data results from an extensive data collection process. It begins with information on all organizations in the Bureau van Dijk Mint Global database that have at least 50 employees in the U.S. and listed websites. Each organization's estimated number of employees, revenue, industry, and headquarters location are available.⁹

The Universal Resource Locator (URL) for each organization between 2000 and 2018 is matched with information from the Internet Archive (IA) Wayback Machine. The IA, a non-profit organization, has routinely scanned millions of publicly facing websites for the past two decades and taken snapshots of the content on those sites. When an individual connects to a website, the server software that hosts the site responds with the site's content and metadata about the server software. This metadata often contains the name of the server software and the server software version number (e.g., Apache 1.3.6). The responding server also communicates its IP address, a sequence of numbers indicating where the server is located. The IA collects and stores this metadata, the IP addresses, and the date of each scan. We compiled the server software name, version number, IP address, and the date recorded in the metadata for each IA scan of the firms in the sample of U.S. organizations.

_

⁹ An organization in our dataset is mapped to a website domain. Two organizations with the same website domain are treated as part of the same organization.

¹⁰ Users have a choice regarding how much information their server response headers show about their server software, ranging from no information to complete information, including the name, version, and operating system. Setting anything less than showing the server's name and version is not recommended. As the ASF puts it, "... [Obscuring server header] makes it more difficult to debug inter-operational problems. Also, note that disabling the Server header does nothing to make your server more secure. The idea of 'security through obscurity' is a myth and leads to a false sense of safety." See https://httpd.apache.org/docs/2.4/mod/core.html#servertokens.

It is important to note that the IA's scanning frequency is irregular. Sometimes, a site is scanned multiple times within a month; at other times, it may be scanned only once over several months. We retain only the first scan of any organization with multiple scans. For sites scanned less frequently than monthly, this irregularity poses challenges in precisely measuring when updates occur. Although this does not affect much of the empirical analyses, the empirical study of how quickly organizations respond to available patches will be limited to a subset of organization months that underwent frequent scans, where the time to patch adoption can be precisely measured.

Also note that while this data encompasses the usage and updates of other server software, including Microsoft's IIS, the empirical analysis will focus on Apache due to the abundance of publicly available information regarding its vulnerabilities, fixes, and feature enhancements for each version.

We supplement this data source with ancillary data describing each Apache version's vulnerabilities and other features of the organization and website characteristics.

4.2. Apache version characteristics, including vulnerability and fix status

When collecting data on Apache versions, it is necessary to understand how the versions are numbered. Apache versions are identified by three numbers separated by dots, for example, Apache 1.3.37. The first two numbers, such as Apache 1.3, represent the *major* version. Each major version introduces significant improvements in performance and functionality. Apache has had several major stable releases, including Apache 1.3 in 1998, Apache 2.0 in 2002, Apache 2.2 in 2005, and Apache 2.4 in 2012. The ASF simultaneously makes minor updates to various major versions, providing vulnerability fixes and incremental improvements. The third number in the version denotes the *minor* version within the major version. For instance, Apache 2.4.1 was released in February 2012, followed by 2.4.2 in April and 2.4.3 in August of the same year.

For each minor version, it is possible to gather information about its vulnerabilities from the ASF and NIST, including each vulnerability's severity, the date it was reported, the date it was disclosed to the public, and the release dates of new versions that fix the vulnerability. This enables determining whether each observation of an Apache minor version in the server usage panel had a *reported*, *disclosed*, *or fixed* severe security vulnerability at any given time and whether an updated major or minor version addressing the vulnerability was available then. In addition to vulnerabilities, we parsed Apache's changelogs, which are documents summarizing

changes made in each software version update, to obtain the number of new and improved features added to each new minor version compared to the previous minor version.

4.3. Organization Characteristics

While the Bureau van Dijk Mint Global database provides a cross-sectional snapshot¹¹ of the estimated number of employees, revenue, industry, and location for all organizations in the sample, the publicly traded firms in the sample have additional data about their operations available on an annual basis. The data for these firms come from Compustat and cover the full panel of U.S. public firms annually. This data contains a wide range of organizational characteristics, such as total assets, capital expenditure, cash flow, and income, allowing us to examine organizational factors that might affect updating decisions. The data's temporal dimension also enables us to study the effects of financial changes within organizations. However, using this data source significantly reduces the sample size, given that only a small fraction of organizations in the sample are public firms.

Additional organizational characteristics are relevant to cybersecurity. The scale and complexity of an organization's IT operations are measured by the number of personal computers owned, the number of IT staff, the IT budget, and the software budget from Harte Hanks for 2017. Data from Harte Hanks also measures whether a subset of organizations outsourced their IT operations between 2005 and 2009.¹²

To examine if data breach disclosures by organizations in the same geographic or industry sectors prompt others to secure their software, the data is matched with data from Privacy Rights Clearinghouse's Data Breach Chronology, which is, to our knowledge, the most comprehensive public source for breach information. In the U.S., data breach notification laws are enacted across all states, with most states adopting these laws in 2005 and 2006. This data source aggregates disclosures from media, state attorneys general offices, and breach disclosure trackers. It includes 2,366 breaches reported from 2005 to 2018, detailing the organization, disclosure date, state, and industry. For 63% of these breaches, the number of affected records was also reported.

¹¹ Taken on August 28, 2018.

¹² Ideally, we would have liked to have these variables for every organization year from 2000 to 2018, matching the span of our server usage panel. However, Harte Hanks expanded their data collection gradually over time, and data in early years had limited mapping with our panel. The firm also only compiled data on IT outsourcing for a select group of organizations during 2005-2009.

4.4. Website Characteristics

To gauge an organization's website traffic, we obtained Alexa's traffic rankings for the top one million websites annually from 2010 to 2018. 13

The IP address for a website enables the determination of whether an organization's website server software is likely cloud-based. The IP addresses are publicly available for Amazon Web Services (AWS), Microsoft Azure, and Google Cloud Platform. ¹⁴

For a subset of the organizations' websites in the dataset, we have data on the web technologies used from 2016 to 2018 gathered from the HTTP Archive, which analyzes websites' technical attributes using an open-source tool developed by Wappalyzer. The data captures technology categories fundamental to website architecture and those supporting monetization and e-commerce, such as marketing automation and payment processors. This information helps us construct proxies for the websites' technical complexity and the organizations' intent to monetize their websites, with the number of web technologies indicative of technical complexity and monetization tools suggesting a significant value at risk from security vulnerabilities.

Below, we look at our three main measures of interest—prevalence of security vulnerabilities in installed and actively used server software, the *determinants* of firm decisions regarding whether to install software updates, and the *responsiveness* of firms to attributes of the updates released—and offer the sample construction, empirical strategy, results, and policy implications for each.

5. Prevalence

5.1. Sample Construction

We apply two restrictions to the server usage panel dataset to study the prevalence of severe security vulnerabilities in organizations using Apache. First, the data set retains only the observations where Apache was used as the server software, excluding data related to other server software like IIS and Nginx. Second, the analysis applies only to observations where the

¹³ We are unable to obtain this data before 2010.

¹⁴ We used snapshots of IP addresses associated with AWS, Microsoft Azure, and Google Cloud Platform taken on March 25, 2020, August 13, 2023, and August 14, 2023, respectively. Historical IP ranges of these cloud services are not available to the best of our knowledge.

¹⁵ Ideally, we would have liked to have these variables for every organization-year from 2000 to 2018, matching the span of our server usage panel. The HTTP Archive, however, only began applying Wappalyzer's analysis tool to extract the technologies present on websites starting in 2016.

complete Apache version number has been captured in the format of three numbers separated by dots. Although the ASF recommends that Apache respond to requests by revealing its full software version number, sometimes organizations either do not display the Apache version number or only show the major version, likely to conceal the exact software version they are using. The complete version number is crucial for mapping each version to its associated vulnerabilities. Applying these restrictions yields 4.9 million organization-month observations from 150,836 organizations. Creating the sample for the prevalence analysis requires combining this refined server usage panel with data on Apache version characteristics, such as the number of reported, disclosed, and fixed vulnerabilities over time. Summary statistics of this sample are provided in Table 2.

5.2. Empirical strategy

Analyzing prevalence across organizations requires aggregating at the monthly level and utilizing line plots to document the extent and distribution of security vulnerabilities in the Apache server software used by organizations from 2000 to 2018. These plots show the proportions of organizations using Apache with reported, disclosed, and fixed severe security vulnerabilities each month.

Analyzing the proportion of organizations with reported vulnerabilities is informative because these vulnerabilities are known to at least a small group of security experts, and the proportion represents the stock of organizations with vulnerable server software. Assessing the proportion with publicly disclosed vulnerabilities is critical; malicious parties could easily exploit this information to target organizations using server software with these vulnerabilities, thus highlighting the pool of organizations at risk of attack. Lastly, examining the proportion with fixed vulnerabilities sheds light on the stock of organizations that are slow to apply patches, providing empirical evidence contributing to the debate on the benefits and costs of mandated vulnerability disclosures.

5.3. Results

Figure 1(a) depicts the proportion of organizations using Apache versions with reported severe security vulnerabilities over time. This plot is generated by aggregating across organizations the binary indicator variable, $severeBugReported_{it}$, which signifies whether severe security vulnerabilities have been reported for an organization-month. The figure

demonstrates that a significant fraction of organizations' servers operated with these vulnerabilities throughout the sample period. Over almost 20 years, the proportion of firms operating with these vulnerabilities averaged 68%, reaching nearly 100% between December 2015 and June 2017. This peak corresponds with the discovery of a critical security vulnerability (identifier: CVE-2017-7679) in a module responsible for assigning content metadata to HTTP responses. This finding indicates a high prevalence of organizations using Apache with known vulnerabilities.

Figures 1(b) and 1(c) further decompose Figure 1(a) into the proportions of firms with reported but undisclosed vulnerabilities and those with reported and disclosed vulnerabilities, respectively. This analysis helps assess whether the high prevalence of known vulnerabilities was due to slow disclosures by the ASF or organizations continuing to use vulnerable software even after disclosures.

As shown in Figure 1(b), no organizations reported undisclosed vulnerabilities for most months, suggesting that disclosures occurred swiftly after reports within the same month. In some instances, disclosures did not occur in the same month as the reports but were still relatively prompt. This corresponds to the spikes, or the rapid increase and decrease in the proportion of organizations with undisclosed vulnerabilities observed between 2002 and 2010. One exception is from December 2015 to June 2017, when a significant proportion of organizations were affected by the reported but undisclosed vulnerability CVE-2017-7679. The ASF received this report in November 2015 but did not disclose and fix it until June 2017.

In contrast to Figure 1(b), Figure 1(c) aligns closely with Figure 1(a), indicating that most organizations operating vulnerable Apache software did so not because of delayed disclosures by the ASF but because they continued to use the vulnerable software after disclosures were made.

Figure 2(a) depicts the proportion of organizations using Apache versions with disclosed severe security vulnerabilities over time. The line plot is identical to that in Figure 1(c). It is generated by aggregating the binary indicator variable, $severeBugDisclosed_{it}$, which signifies whether severe security vulnerabilities have been disclosed for an organization-month. The figure shows that a significant fraction of organizations' servers operated with these vulnerabilities throughout the sample period. Over nearly 20 years, the proportion of firms operating with these vulnerabilities averaged 60%, peaking at 98% in October 2014. This peak corresponds to discovering a critical security vulnerability (identifier: CVE-2004-0885) in a

module responsible for strong cryptography. The finding suggests a high prevalence of organizations using Apache with known and disclosed vulnerabilities. While the exploitability of these vulnerabilities depends on the precise configuration of each firm's server configuration, the high prevalence of vulnerabilities suggests that firms are operating outdated and potentially insecure server software.

Figures 2(b) and 2(c) further decompose Figure 2(a) into the proportions of firms with disclosed but unfixed vulnerabilities and those with disclosed and fixed vulnerabilities, respectively. This analysis helps to assess whether the high prevalence of disclosed vulnerabilities was due to the ASF not offering fixes or because organizations continued to use vulnerable software even after fixes were available. The former would suggest security mismanagement on the part of the ASF, which would call for policies for better governance of software developers. The latter would suggest security mismanagement by the organizations themselves, which would call for policies that promote more effective patching behaviors.

Although a substantial number of organizations dealt with disclosed vulnerabilities without fixes between 2003 and 2005, as shown in Figure 2(b), almost no organization faced disclosed but unfixed vulnerabilities for most months from 2006 to the end of the sample period. This indicates that the ASF has become more diligent and effective in managing disclosures and fixes as it has matured.

In contrast to Figure 2(b), Figure 2(c) is closely aligned with Figure 2(a). Just as with Figures 1(a), (b), and (c), this shows that most organizations operating vulnerable Apache software did so not because the ASF delayed fixes but because they continued to use the vulnerable software after fixes were made available.

Figure 3 further dissects Figure 2(c), displaying the fraction of organizations using Apache versions with one or more disclosed and fixed severe security vulnerabilities. The blue line plot in Figure 3 is identical to the line plot in Figure 2(c), generated by aggregating the binary indicator variable. $severeBugFixed_{it}$, This signifies whether the Apache version used by the organization that month had severe security vulnerabilities already fixed in newer versions. Alarmingly, 57% of organizations in the sample used Apache versions with disclosed severe security vulnerabilities in which fixes were potentially available. Yet these organizations did not adopt the fixed software. The proportion of these organizations almost never fell below 20% throughout the sample period.

Additionally, Figure 3 shows that many organizations did not adopt fixed software. The variable captures the number. $numSevereBugFixed_{it}$. On average, organizations utilized Apache versions with two fixed severe vulnerabilities; a notable proportion operated with six or more such vulnerabilities. This highlights a considerable issue with organizations' inaction. Apache fixed the software, but the companies didn't make the local patches necessary to complete the fix.

Figure 3 plots the fixed release dates, represented by vertical dotted lines. For example, in July 2006, the ASF released Apache 1.3.37, Apache 2.0.59, and Apache 2.2.3. These releases fixed a severe vulnerability (identifier: CVE-2006-3747) that allows remote attackers to cause a denial-of-service attack. The red oval in Figure 3 highlights the update window following the July 2006 release. A closer examination of that update window reveals that many organizations took months or even years to update to those releases. The fraction of organizations using problematic versions of Apache peaked at 92% following the release, but the rate declined by only 1.7% per month over the next three years. By mid-2009, over 30% of organizations were still operating vulnerable versions of the Apache server software.

5.4. Policy implications

The empirical results on the prevalence of Apache vulnerabilities offer abundant policy implications. The analysis reveals that the ASF has generally been prompt in disclosing and addressing vulnerabilities upon their discovery. Instances where severe vulnerabilities remained undisclosed for more than two months post-reporting are scarce in the dataset. Additionally, while there was a period between 2003 and 2005 during which the ASF took longer to patch disclosed vulnerabilities, there has been a marked improvement in its security practices since 2006, with such instances becoming exceedingly rare. Their actions align with Arora, Caulkins, and Telang's (2006) recommendation to disclose vulnerabilities quickly to accelerate the development of patches and updates.

Conversely, the results highlight a significant risk linked to quick and/or compulsory disclosure stemming from users' delayed actions in applying available fixes to vulnerable software. Although swift disclosure may motivate software developers to produce fixes more quickly, it also risks leaving many users who are slow to respond susceptible to exploitation by malicious entities.

6. Determinants of Fixing Vulnerabilities

6.1. Sample Construction

To study the determinants of organizational differences in vulnerability prevalence, we combined the analysis sample for prevalence with various organizational and website characteristics that serve as explanatory variables. Table 2 shows summary statistics for the merged sample used in this section for analyzing the determinants of vulnerabilities in firms' server software.

Key outcome variables are $severeBugFixed_{it}$ and $numSevereBugFixed_{it}$, which capture the extent and number of fixed severe vulnerabilities in the Apache versions organizations use. $severeBugFixed_{it}$ is the binary indicator variable that indicates whether severe security vulnerabilities in the Apache version used by the organization were already fixed in the given month. $numSevereBugFixed_{it}$ is a count variable, tallying the number of fixed severe security vulnerabilities in the Apache version used by the organization in the given month. These variables are the best at capturing differences in organizations' actions or inactions regarding updating and keeping their software secure compared to the number of reported or disclosed vulnerabilities, which are also influenced by the actions of the ASF.

A range of explanatory variables captures the cost of patching, as motivated by August and Tunca (2006). The binary indicator variable $newUser_{it}$ signifies whether the observation represents the first instance of the organization's website using Apache, as captured by the IA. Unlike incumbent users of server software, new users of Apache are not constrained by previous technical investments and should, therefore, face lower costs when adopting the latest, vulnerability-free software versions. The variables PCs_i , $ITBudget_i$, and $SoftwareBudget_i$ reflect the number of computers, the IT budget, and the software-specific budget an organization has at a given cross-section, retrieved from [??] the Harte Hanks data from 2017. These variables proxy for the overall scale and complexity of IT operations within an organization. Specifically for the technical complexity of the website that the server software hosts, we utilize HTTP Archive's website technology data to construct variables $techCategories_i$ and $techs_i$ to denote the number of technology categories (e.g., JavaScript Frameworks, Marketing Automation) and

the individual technologies (e.g., jQuery, Google Analytics) embedded within the website. 16 The variables $outsourced_i$ and $cloud_{it}$ indicate whether the organization has outsourced its IT operations and whether the server software was likely hosted on a cloud provider, AWS, Azure, or Google Cloud. 17 Outsourcing and cloud hosting reduce an organization's day-to-day costs of monitoring and securing software, as many of the maintenance tasks are delegated to third parties.

A few variables reflect both the cost of patching and the value at risk, allowing us to evaluate how organizations balanced the cost versus the benefit of patching. One such variable is $highTraffic_i$, which is a binary indicator variable that captures whether a website experienced high traffic based on Alexa rankings. Another is $monetization_i$, a binary indicator variable determining whether a website has embedded monetization technologies for e-commerce, marketing automation, and payment processing. A high-traffic website or an e-commerce site is valuable to an organization, but patching is also more expensive due to the potential for disrupted services.

Additional variables reflect the value at risk from not patching, which was also motivated by August and Tunca (2006). These include binary indicator variables $finance_i$, $healthcare_i$, and $govt_i$ For organizations in the finance or healthcare sectors or public administration. These sectors are likely to process highly sensitive personal data, representing an exceptionally high value at risk. This also includes $countBreachState_{it}$ and $countBreachIndustry_{it}$, which capture the number of data breaches in the same state or industry as the organization under observation in a given month. The variables $noAffectedBreachState_{it}$ and $noAffectedBreachIndustry_{it}$ capture the total number of personal records reported to have been compromised in those breaches. While data breaches do not directly increase the value at

1.

 $^{^{16}}$ We observe these technology categories and technologies embedded for only a few organizations between 2016 and 2018. We use the total number observed during that period for each organization so each variable only has the organization subscript i.

 $^{^{17}}$ We observe outsourcing status for only a few organizations between 2005 and 2009. We define $outsourcing_i$ =1 if the organization has outsourced at any point during 2005—2009 so the variable only has the organization subscript i. We also define a binary indicator variable $outsourcingMissing_i$ to indicate whether outsourcing information is missing for an organization. This variable will help us to keep observations with missing outsourcing information in regressions, allowing us to preserve a relatively large sample size and statistical power.

¹⁸ We have Alexa rankings from 2010 to 2018. We define a website as high traffic if it has had a ranking above 100,000 at any point during 2010—2018.

¹⁹ This variable is defined as 1 if the website has embedded any of the technology categories "analytics," "tag managers," "advertising networks," "marketing automation," "e-commerce," and "payment processors" during 2016—2018.

risk for organizations in the same state or industry, they could heighten the awareness of the value at risk for these organizations. Additionally, the estimation includes standard organizational characteristics such as employment, revenue, and whether the organization was publicly listed. For publicly listed firms, additional variables are included, such as the firm's total assets and income each year.

6.2. Empirical Strategy

A linear probability model can estimate how different organizational and website characteristics affect whether the organization used an Apache version with fixed severe security vulnerabilities. The endogenous variable is $severeBugFixed_{it}$. The regression specification is given by:

$$severeBugFixed_{it} = \beta_0 + \beta_1 X_{1,it} + \dots + \beta_k X_{k,it} + \delta_t + \epsilon_{it}, \qquad (1)$$

where $X_{1,it}$, ..., $X_{k,it}$ represents the explanatory variables, including organizational and website characteristics, and delta sub t denotes month-fixed effects. The inclusion of month-fixed effects is motivated by the patterns observed in Figure 3, which show that the months in which fixes were released resulted in significant shifts in the prevalence of fixed severe vulnerabilities among organizations.

A Poisson regression model can estimate how different organizational and website characteristics influence the number of fixed severe security vulnerabilities in the Apache version used by organizations. The endogenous variable is $numSevereBugFixed_{it}$. Under this model, $numSevereBugFixed_{it}$ is presumed to follow a Poisson distribution, with the parameter $\lambda_{it} = E(numSevereBugFixed_{it})$ being a log-linear function of the explanatory variables $X_{1,it}, ..., X_{k,it}$:

 $\log\left(E(numSevereBugFixed_{it})\right) = \beta_0 + \beta_1 X_{1,it} + \dots + \beta_k X_{k,it} + \delta_t + \epsilon_{it}. \tag{2}$ Like the linear probability includes organizational and website characteristics, and delta sub t denotes, ..., $X_{k,it}$ includes organizational and website characteristics and delta sub t denotes month-fixed effects. ²⁰

²⁰ While the outcome variable $numSevereBugFixed_{it}$ shows evidence of overdispersion (it has a mean of 2.012 and a standard deviation of 2.312 as shown in Table 3), a fixed effects Poisson model is robust to overdispersion and is preferred over a fixed effects negative binomial model due to its robustness to both over- and underdispersion,

6.3. Results

Table 4 presents regression results for the linear probability model and the Poisson model across different combinations of explanatory variables. Columns (1) and (3) show the regression results for the linear probability and Poisson models, respectively, when only the most well-populated explanatory variables are included. This approach enables the preservation of a large sample of organization months. Columns (2) and (4) introduce less well-populated explanatory variables. Lastly, Columns (3) and (6) show the results from adding organization-fixed effects to both models. Although the regressions utilize two distinct outcome variables, and sample sizes for each specification differ significantly, the results are remarkably consistent across the various specifications. Appendix Table A4 includes variables from Compustat about public firms, which effectively restricts the sample to these firms. The results from public firms are very similar to those from the full sample.

Variables capturing the cost of patching are good predictors of both the presence of fixed severe vulnerabilities and the number of fixed severe vulnerabilities. Being a new user is associated with a decrease of 3.3 to 4.7 percentage points in the probability of having any fixed severe vulnerabilities and with a 11.7% to 17.6% reduction²¹ in the number of fixed severe vulnerabilities. Cloud-hosting is linked to a 10.9 to 19.9 percentage point decrease in the probability of having fixed severe vulnerabilities and a 33.9% to 41.3% decrease²² in the number of fixed severe vulnerabilities. Both variables are significant at the 1% level across all specifications. While other variables that capture the cost of patching do not provide estimates as significant or consistent across different specifications, the direction of the estimates generally supports the hypothesis that organizations with higher patching costs tend to have a higher prevalence of vulnerabilities. Organizations with more PCs are more likely to have fixed severe vulnerabilities and a greater number of them, though the effect is not economically significant. Similarly, organizations that have not outsourced their IT operations are more likely to have fixed vulnerabilities and more of them, compared to those that have outsourced or about which we lack information. Evidence regarding website technical complexity is inconclusive, as

-

heterogeneity in the variance-mean relationship across observations, violations of conditional independence, and serial correlation, which the fixed effects negative binomial model is not robust to (Wooldridge, 1999).

²¹ From Column (6) of Table 4, $1 - \exp(-0.124) = 11.7\%$. From Column (4), $1 - \exp(-0.194) = 17.6\%$.

²² From Column (5) of Table 4, $1 - \exp(-0.414) = 33.9\%$. From Column (6), $1 - \exp(-0.532) = 41.3\%$.

estimates for $techCategories_i$ and $log(techs_i + 1)$ are close to zero for the full sample and do not have a consistent direction for the public firms.

For variables that capture both the high cost of patching and the high value at risk, this evidence suggests that organizations are more concerned about the cost of patching than the value at risk. The estimates for $highTraffic_i$ are positive and highly significant across all specifications. These estimates indicate that websites with high traffic are 2.6 to 5.0 percentage points more likely to have fixed severe vulnerabilities and at least 3.7% more of those vulnerabilities.²³ Although the estimates for $monetization_i$ are less significant, the positive direction of these estimates is consistent with the hypothesis that the cost considerations of patching outweigh the considerations regarding value at risk.

The results also suggest that the value at risk does not have a strong association with the prevalence of fixed severe vulnerabilities. Although the finance, healthcare, and public administration sectors are all likely to handle sensitive personal data, their impact on vulnerability prevalence does not have a consistent direction. Data breach disclosures within the same state or industry have an economically insignificant impact with inconsistent directionality. We have considered a range of organizational characteristics, such as revenue and whether the firm is publicly listed. Appendix Table A4 includes various characteristics of publicly listed firms, such as income and cash flow. However, none of these variables appear to be significant. The only notable finding is that larger organizations are more likely to have fixed severe vulnerabilities present in their severe software and to have a greater number of them.

In addition, the estimates suggest that a significant amount of unobserved organizational factors also influenced vulnerability prevalence. While the cost of patching is a strong predictor of prevalence, the magnitude of each individual estimate is small compared to the overall prevalence of vulnerabilities. Moreover, despite including a wide array of observed organizational and website characteristics, the explained variance in the outcome variable severeBugFixed_{it}, as indicated by the R-squared value, is only moderate. In Column (3) of Table 4, the inclusion of organization-fixed effects substantially increased the R-squared value. These results suggest that unobserved variations between organizations are likely important drivers of differences in prevalence.

²³ From Column (5) of Table 4, $\exp(0.036) - 1 = 3.7\%$.

6.4. Policy implications

These results carry substantial policy implications. First, they relate to theoretical models concerning user incentives for patching, such as those by August and Tunca (2006). The cost of patching and the value at risk are crucial elements of these models that affect the optimality of different incentive schemes to encourage users to patch vulnerable software. The findings suggest that organizations with lower patching costs are more likely to patch. At the same time, those with a higher value at risk do not necessarily exhibit a greater likelihood of patching. Indeed, the findings imply that policies aimed at increasing the perceived value at risk, such as a usage tax, may be less effective than policies aimed at reducing the cost of patching, such as patching rebates.

The results could also assist policymakers in developing targeted policies. For instance, the findings suggest that data breach disclosures or marketing campaigns designed to raise awareness of the value at risk from cyberattacks are unlikely to be effective. In contrast, policies that reduce the cost of patching, such as providing IT training, may prove more effective. Among these policies, workshops or subsidies that help organizations migrate their software services to third-party professionally managed services and the cloud could significantly reduce the prevalence of vulnerabilities.

Furthermore, the organizational effect is an important consideration for policymakers, as organizations may exhibit persistence in their security management practices. This persistence suggests that policy interventions targeting organizations could have limited effectiveness.

7. Responsiveness

7.1. Sample Construction

Section 6 examines cross-sectional differences in the prevalence of vulnerabilities and the determinants of organizations' willingness to implement patches. However, the analysis in that section does not provide insights into the determinants of how quickly organizations respond to new updates that address security threats post-release. The diversity of factors affecting the speed of responsiveness may align with those influencing vulnerability prevalence at the cross-section; however, this topic deserves its own investigation. Such an analysis could uncover additional factors that enable organizations to address severe vulnerabilities with software updates more

promptly at certain times than at others—for example, the characteristics of the updates themselves.

The approach involves analyzing the effects of various characteristics of the updates and the characteristics of the organization and its website on the time taken to adopt vulnerability fixes. To construct the sample for this analysis, we identify the relevant time periods following the release of each critical update for the software versions used by organizations within the previous sample to compile a targeted analysis sample for responsiveness.

Figure 4 provides a visual explanation of the construction of the responsiveness sample. Panel (a) displays observations from the determinants of vulnerabilities sample for the firm Adobe. Each observation details the organization's identifier *i* ("adobe.com"), the month of IA capture *t*, and the version of Apache. The sample also includes other organizational and website characteristics not displayed in Panel (a). The dataset records Adobe's use of Apache from March 2001 to December 2002. These observations will be utilized to construct observations in the responsiveness sample pertaining to Adobe. It should be noted that, due to the irregular capture frequency of the IA, there are gaps in our observations, such as in February 2002 and April 2002 for Adobe.

It is possible to know whenever a new version that fixes vulnerabilities in a particular Apache version becomes available based on the data on Apache security vulnerabilities. Between March 2001 and December 2002, two releases addressed the severe vulnerabilities in the Apache versions Adobe used. One of them was the release of Apache 1.3.24 in March 2002, which fixed a severe vulnerability (identifier: CVE-2002-0061) in the version in use, Apache 1.3.19, that allowed remote attackers to execute arbitrary commands. Panel (a) shows that by July 2002, Adobe.com had been updated to a version above 1.3.24, which fixed the vulnerability.

Using the relevant observations from Panel (a) for this updating event, as shown in the red box in Panel (a), we can construct one observation in the responsiveness sample. This observation is shown in the red box in Panel (b). The $timeToFix_{ir}$ variable represents the number of months it took the organization to adopt the fix, where the r subscript indexes the release (version 1.3.24 in March 2002). The $timeToFix_{ir}$ variable in this case equals 4. The $fixed_{ir}$ The variable is a binary indicator, where it equals 1 if the organization adopts the fix and equals 0 if it does not adopt the fix by the final recorded observation (i.e., this updating cycle is right-censored). $fixed_{ir}$ in this case is 1. The variable $severeFixed_{ir}$ represents the number of

severe vulnerabilities that the new update could fix for the version in use, which equals 1 in this case.

Another release that addressed severe vulnerabilities for Adobe was the release of Apache 1.3.27 in October 2002, which fixed two severe vulnerabilities (identifiers: CVE-2002-0839 and CVE-2002-0843) in the version in use, Apache 1.3.26. We only observed Adobe's Apache usage up to December 2002, and no updates occurred until then, as shown in the green box in Panel (a). This allows us to construct another observation in Panel (b), where $timeToFix_{ir}$ is recorded as 2, and $fixed_{ir}$ is set to 0 to reflect that the updating cycle is right-censored. The number of severe vulnerabilities fixed in that release, $severeFixed_{ir}$, is 2.

Another point to consider in the sample construction is handling gaps in IA captures. Although Figure 4 indicates gaps in IA captures for Adobe in February 2002 and April 2002, these did not affect the sample construction. We were able to deduce the time to fix it precisely. Such precision is not attainable when significant gaps in an updating cycle occur. An updating cycle is observed to start with the release that fixed severe vulnerabilities in the version in use and is deemed to end with the first observed use of a version above that release. Suppose significant gaps are present within this cycle. In that case, it is conceivable that the organization might have been using the updated version for a substantial period before it was recorded in the data. Hence, the sample only uses updating cycles for which there are IA captures at least once every two months on average to construct observations for the responsiveness sample.

In addition to the variables mentioned above, the analysis includes a range of additional variables to capture the characteristics of the updates and the organization and website characteristics in the responsiveness sample. Table 5 presents the summary statistics for this sample.

Numerous variables represent the characteristics of the updates for each release that fixed severe vulnerabilities. The variable $nonSevereFixed_{ir}$ represents the number of non-severe vulnerabilities release r fixed in organization i's version in use at the time of the release. Meanwhile, $featureChanges_{ir}$ represents the cumulative number of feature changes between the version organization i used and release r. Fixes for minor vulnerabilities and feature changes can be valuable, but they can also add complexity and cost to software updates.

The variable $sameMajorVersion_{ir}$ is a binary indicator that equals one if the version in use and release r belong to the same major version (e.g., the version in use is 1.3.19, and the fix

is released in 1.3.24) and equals 0 otherwise (e.g., the version in use is 1.3.19 and the fix is released in 2.0.37). Updates within the same major version represent small incremental changes that are less costly to install.

The binary indicator variables $highImpact_{ir}$ and $highExploitability_{ir}$ indicate that the update fixed vulnerabilities with high impact and high exploitability, respectively. High-impact vulnerabilities, which scored 10 out of 10 in impact according to NIST's scoring rubric, could result in total disclosure of information, a total compromise of system integrity that allows attackers to modify any files, and a complete shutdown of the system. High exploitability vulnerabilities, which scored 10 out of 10 in exploitability by the same rubric, would allow attackers to attack over the network without authentication requirements, and the attack has low complexity once an attacker has gained access to the target system.

The variable $notOSSpecific_{ir}$ is a binary indicator that indicates that at least one of the severe vulnerabilities fixed by the release is not specific to a particular operating system, making the vulnerability more general.

A variable, $prevTimeToFix_{ir}$, represents the time the organization took to update to the preceding release that [?] addressed severe vulnerabilities. It investigates the persistence of organizations in their vulnerability patching practices. If organizations were not persistent, those that were slow to patch in the previous updating cycle should aim to patch more rapidly in the current cycle to compensate. Conversely, suppose organizations are burdened with consistent organizational costs, such as a poorly organized IT department. In that case, they will likely exhibit similar delays in the current cycle if they were slow previously.

The responsiveness sample also includes the range of organization and website characteristics, for example, $newUser_{it}$ and PCs_i . Whenever these variables carry a time subscript, the value of the variable on the release date is used to fill that variable in the responsiveness sample.

7.2. Empirical Strategy

Because the outcome of interest is a time-to-event variable—the amount of time from the release until the organization adopts the release—survival models can estimate what predicts faster or slower patching. We first estimate the standard Cox proportional hazards regression model, specified as follows:

$$h_{ir}(t) = h_0(t)ex \, p(b_1 X_{1,ir} + b_2 X_{2,ir} + \dots + b_j X_{j,ir}), \tag{3}$$

where $h_{ir}(t)$ is the hazard function, representing the expected number of updates to the fixed version given that the vulnerable version has survived for t months. $h_0(t)$ is the baseline hazard and represents the hazard when all the explanatory variables $X_{1,ir}, ..., X_{j,ir}$ are equal to zero. If some explanatory variables carry a time subscript t or y that varies within an updating cycle, the value of the variable on the release date is used in the regressions.

While the model described above examines differences in the rates at which organizations patch their vulnerable server software based on observed updates and organizational and website characteristics, it does not account for unobserved differences in the organizations' security management practices, which could lead to reverse causality issues. Specifically, the model in Equation (3) assumes the baseline hazard. $h_0(t)$ is the same for all organizations. However, organizations that are persistently slow to update for unobserved reasons are more likely to use older versions of Apache, which have more severe security vulnerabilities that need fixing. If we assume a uniform baseline hazard across all organizations and estimate a Cox model, the estimate for $severeFixed_{ir}$ would likely be biased downward. Consequently, we might incorrectly conclude that a release addressing a greater number of severe security vulnerabilities would be associated with a longer time to adopt the release.

To control for unobservable differences in organizations' security management practices, the preferred specification is a stratified Cox model, which allows each organization to have a different baseline hazard:

$$h_{ir}(t) = h_{0i}(t) \exp\left(b_1 X_{1,ir} + b_2 X_{2,ir} + \dots + b_j X_{j,ir}\right),\tag{4}$$

where the i subscript in $h_{0i}(t)$ denotes stratum for organization i. Under this model, the effect of a variable is identified by the changes to that variable within an organization across different releases. r.

The estimated effect of update characteristics on the time-to-fix from Equation (5) is causal because the reporting, disclosures, and release of fixes for severe security vulnerabilities and the characteristics of each update released are plausibly exogenous to an organization's IT staff. While formally testing exogeneity assumptions is generally challenging, the crucial assumption in this context is intuitive. Most web developers and IT professionals are

not directly involved in developing Apache server software or in its vulnerability handling process. Although they can potentially influence the process through bug discovery and reporting, and the more they interact with the software, the more likely they are to find bugs, the influence of any single organization (aside from the ASF) is negligible compared to the total global interactions with the software. To ensure that individual organizations' actions do not disproportionately affect the vulnerability handling and release process of Apache server software, we examined the data on who was credited with discovering or reporting each vulnerability to the ASF. Aside from the ASF Security Team staff, there is almost no overlap in the names and organizational affiliations of the reporters.

7.3. Results

Estimation results are presented in Table 5 and provide evidence that the stratified Cox model is preferable. Column (1) displays the standard Cox regression results, using only update characteristics as explanatory variables. As expected, the estimate for $severeFixed_{ir}$ is biased downward due to unaccounted-for organizational effects. Column (2) incorporates more comprehensive organization and website characteristics, and Column (3) includes additional, less populated organizational and website characteristics. As these controls are added, the coefficient becomes increasingly positive. This suggests that accounting for organizational effects is crucial for mitigating reverse causality issues and ensuring correct inferences. Column (4) presents the estimates from the stratified Cox model, stratified at the organization level, using only a small subset of explanatory variables. Column (5) presents the stratified Cox model with additional controls for time-varying organization characteristics. In both specifications, the estimates for $severeFixed_{ir}$ are large, positive, and highly significant. This suggests that an increase in the number of severe vulnerabilities a release fixes leads organizations to respond to the release more quickly.

Another piece of evidence supporting the effectiveness of the stratified Cox model in controlling for unobserved organizational effects comes from the estimates of the variable. $prevTimeToFix_{ir}$. This variable captures the persistence of organizations in their patching behavior between adjacent updating cycles. The estimates for this variable are large, negative, and highly significant in the standard Cox models. They suggest that a one-month increase in the time to fix in the previous updating cycle for an organization would be associated with at least a

1.8% decrease in the expected hazard of updating in the current cycle.²⁴ The estimates become economically negligible in the stratified Cox models, although they retain statistical significance.

Based on the preferred specification, the stratified Cox models, organizations have varying levels of responsiveness to different characteristics of updates. For the same reasons discussed in Section 7.2, the estimates are causal.

The estimates show that organizations are responsive to fixing severe vulnerabilities that enhance the security of their software. An additional severe vulnerability being fixed in a new release would result in a 7.6% to 18.5% increase in the expected hazard of updating to that release. ²⁵

Organizations are averse to characteristics of updates that increase the complexity of updating, even when those characteristics offer benefits, such as minor bug fixes and feature improvements. An additional non-severe vulnerability being fixed in the new release would result in a 6.4% to 9.3% decrease in the expected hazard of updating to the release. Furthermore, a 10% increase in the number of feature changes in the release, relative to the version in use, would result in a 0.7% to 0.9% decrease in the expected hazard of updating. This contrast suggests that organizations perceive the benefit of updating to fix severe vulnerabilities to outweigh the cost, which is not the case for non-severe bugs and feature improvements.

Moreover, organizations are significantly more responsive to new releases that consist of small incremental changes to their existing software, as opposed to major upgrades in performance and features. When the release is a minor new version within the same major version as the version in use, organizations exhibit a 215.8% to 226.7% higher expected hazard of updating compared to releases that are part of a different major version.²⁸

²⁴ From Column (3) of Table 5, 1 - exp(-0.018) = 1.8%.

²⁵ From Column (4) of Table 5, exp(0.073) - 1 = 7.6%. From Column (5) of Table 5, exp(0.170) - 1 = 18.5%.

²⁶ From Column (4) of Table 5, 1-exp(-0.066) - 1 = 6.4%. From Column (5) of Table 5, 1-exp(-0.098) = 9.3%.

²⁷ From Column (4) of Table 5, $1 - exp\left(-\frac{0.094}{100} * 10\right) = 0.9\%$. From Column (5) of Table 5, $1 - exp\left(-\frac{0.075}{100} * 10\right) = 0.7\%$.

²⁸ From Column (4) of Table 5, exp(1.150) - 1 = 215.8%. From Column (5) of Table 5, exp(1.184) - 1 = 226.7%.

Furthermore, compared to releases that address highly impactful severe vulnerabilities, organizations are more responsive to those that address highly exploitable vulnerabilities. While the estimates for high-impact vulnerabilities are not consistently significant, a release that addresses highly exploitable severe vulnerabilities is associated with a 26.2% to 31.5% increase in the expected hazard of updating to that release.²⁹

7.4. Policy implications

The results offer important empirical evidence for the policy debate on designing effective vulnerability disclosure policies. These estimates demonstrate that full disclosure is unlikely to be optimal. While organizations respond to releases that announce fixes for severe vulnerabilities, the evidence suggests they avoid releases disclosing fixes for non-severe ones due to the greater costs and complexity of adoption, which outweigh the perceived benefits. Thus, a robust vulnerability disclosure policy that aims to minimize vulnerability exposure, maximize patching behavior, and enhance societal welfare should consider disclosing fixes for severe vulnerabilities but not for minor ones.

Moreover, the empirical evidence suggests that organizations are very cost-sensitive when making vulnerability patching decisions. Announcements of feature improvements could increase the perceived costs and complexity of installation. Software developers should reconsider how much information about feature improvements to disclose to avoid discouraging patching behavior.

Additionally, developers should consider releasing small incremental updates or standalone patches for highly severe vulnerabilities to encourage patching rather than bundling the patch with numerous new features in a major release, which could serve as a deterrent.

Furthermore, when disclosing fixes for severe vulnerabilities in new releases, developers should emphasize the exploitability of the vulnerability. This method is likely more effective than simply discussing the potential impact if the vulnerability were to be exploited.

33

²⁹ From Column (4) of Table 5, exp(0.233) - 1 = 26.2%. From Column (5) of Table 5, exp(0.274) - 1 = 31.5%.

8. Conclusion and Discussion

This study examined installations of updates to address security vulnerabilities in open-source server software used by over 150,000 organizations in the United States between 2000 and 2018. It is the largest data set assembled on security vulnerabilities and updates. The study sought to understand a previously unexplored research question: how prevalent are severe vulnerabilities in server software, what determines the variance in the installation distribution, and how fast do software users respond to the availability of secure versions? Previous research on cybersecurity has primarily focused on the role of the software vendors in providing updates for vulnerabilities and took for granted that users would automatically implement them, an approach that ignores the significant heterogeneity in whether and when software users respond to such updates.

The empirical analysis revealed four critical findings. First, the study finds widespread usage of server software with known vulnerabilities by organizations hosting their websites. In nearly every month between 2000 and 2018, no less than 19% of the Apache servers in use contained a severe security vulnerability. While the exploitability of these vulnerabilities depends on various factors, the high prevalence suggests that there may be many opportunities for malicious actors to exploit organizations' web servers.

Second, the prevalence of vulnerabilities in the software used to host companies' websites is associated more with factors related to the cost of updating than factors related to the value of security. For example, new organizations and organizations using cloud-hosting solutions, both of which likely lower the costs of utilizing up-to-date software, are less likely to have known severe security vulnerabilities in their server software. In contrast, large firms and firms with large amounts of IT are more likely to run server software with vulnerabilities -- even when fixes are available – possibly due to the complexity and costs related to updating that hefty infrastructure. In contrast, firms that stand to lose the most from a cyberattack, such as high-traffic websites and organizations whose websites have monetization technologies, are surprisingly more likely to have vulnerabilities in their software. These findings imply that cost considerations for updating often outweigh the value of decreasing the risk of cyberattack when firms decide whether to update and when to install software updates.

Third, observables cannot easily explain a large variation in the prevalence of vulnerabilities in company server software. For example, an organization's industry, geography,

and website characteristics do not strongly predict the organization's routine regarding whether to allow vulnerabilities to accumulate or install updates in a timely fashion. Instead, persistent, unobservable aspects of organizations explain much of the variation in the presence of vulnerabilities. These unobservable factors may include organizational culture, complementary technologies, external vendor relationships, or other factors for which observational data cannot be easily obtained.

Finally, some attributes of server software updates lead firms to install updates more quickly. A hazard model with stratification accounts for persistent unobservable factors that may influence organizations' update timing. While firms are responsive to updates with security fixes, they are slower to install multifaceted and complex updates. Specifically, firms are slower to install updates with minor bug fixes and feature improvements.

These findings inform previous theoretical work on cybersecurity policy. First, scholars and policymakers have contemplated mandating the disclosure of software vulnerabilities to instigate faster releases of software updates patching vulnerabilities (Arora, Telang, and Xu, 2008). Our data revealed, however, that organizations are slow and unthorough when installing updates. This finding gives reason to be cautious about such a policy. Second, policymakers have considered either providing patching rebates to defray the cost of installing updates or taxing software users to dissuade low-value firms from using software in insecure ways (August and Tunca, 2006). Our finding that the presence of vulnerabilities in server software is associated with high costs of updating implies that software update rebates may be more effective at increasing cybersecurity practices than policies aimed at increasing the value of updating or highlighting the risk of vulnerability. In addition, organizations can take actions that reduce the cost of installing updates, such as hosting their website on a cloud-based platform that assists with installing updates and decreasing the technological complexity of their website. Finally, a long-running theme in cybersecurity literature questions the amount of information software vendors should release about vulnerabilities in their software (Mitra and Ransbotham, 2015). The results of the hazard model analysis reinforce that software vendors can also design the release of software updates in ways that are more likely to have those updates adopted. Specifically, when updates fixing severe vulnerabilities are packaged in an update alone, they are more likely to be installed in a timely manner than if those updates contain feature updates or minor bug fixes.

In addition to informing the previously considered policies, the empirical findings also highlight a new avenue for policymakers and managers concerned with cybersecurity. The finding that much of the variation in the presence of vulnerabilities is explained by persistent unobservable attributes of firms implies that policymakers and managers may wish to focus on organizational routines and culture to improve cybersecurity. For example, managers should consider if a routine that includes updating at regular intervals is beneficial for their organization.

The study does have limitations. First, it only examines Apache web servers. While open-source server software operates on most servers today (Greenstein and Nagle, 2014), installing updates on proprietary server software, especially from software vendors that automatically send software updates to users, may be different. Extensive and detailed data were available because Apache server software is open source, the Apache Foundation is transparent about vulnerability reports, and the Apache Foundation documents and releases information on the contents of every software update. Proprietary software vendors are less transparent about their products and users. Future research on the usage of proprietary software would enable a more complete picture of software user behavior in general.

Second, there are many challenges matching variance in server software decisions at organizations with variance in management practices at those organizations. The observed routines regarding software updates may reflect broader managerial routines or IT investments. While we have attempted to match the data with information in the World Management Survey, the overlap in samples provides limited statistical power for analysis, and the select sample of matching firms constrains the external validity of any findings. Future researchers should seek to find ways to expand on the insights by attempting to understand how managerial practices more broadly influence IT and cybersecurity investments.

This study sets the stage for future research on a variety of cybersecurity-related topics. First, while the data highlight the prevalence of vulnerabilities in server software being used and some of the factors associated with the presence of these vulnerabilities in organizations' software, more research can be done on factors that instigate changes in cybersecurity practices. For example, future research should examine how executive leadership changes, labor market changes for IT professionals, and business cycles impact firms' cybersecurity postures. Second, more research should be done on the effect of cybersecurity service vendors on vulnerabilities. While this seems like a rich area for research, additional data collection on the timing and usage

of these services will be required. Finally, future research should better understand the interaction of firm strategy, the competitiveness of firms' markets, and cybersecurity investment decisions.

Tables and Figures

Table 1 Summary of Data Sources

	Data	Variables	Coverage	Source
Key di	Server software usage panel of U.S. organizations	Server software name (Apache or non-Apache), version number, IP address for the homepages of 200,000+ U.S. organizations with 50 or more employees	Jan 1, 2000August 1, 2018; irregular capture frequency; 17+ million observations	IA
Apac	he version characterist	tics		
(ii)	Apache security vulnerabilities	Each vulnerability's reporting date, version(s) affected, disclosure date, fix date and version, and (when available) the entity credited with reporting	158 vulnerabilities reported before or on August 1, 2018	ASF
(iii)	Severity of Apache security vulnerabilities	Each vulnerability's severity rating (high, medium, or low), and breakdown scores including impact and exploitability	28 vulnerabilities rated high, 123 rated medium, and 7 rated low	NIST
(iv)	Apache version release dates	Each Apache version's release date	115 releases between 2000 and 2018	Authors' compilation
(v)	Apache version feature improvements	Each Apache version's new and improved features from Apache change logs		ASF
Orga	nization characteristic	s		
(vi)	Basic organization characteristics	Location (state), industry (NAICS), the estimated number of employees, and estimated revenue	Cross-sectional snapshot on August 28, 2018	Mint Global by Bureau van Dijk
(vii)	Public firm characteristics	Total assets, capital expenditure, depreciation and amortization, number of employees, cash flow, and net income	Yearly panel between 2000 and 2018	Compustat

(viii)	Organization's IT operations	Number of personal computers, number of IT staff, IT budget, and software budget	Cross-sectional snapshot for the year 2017	Harte Hanks
(iv)	Organization's IT outsourcing	Whether the organization outsourced its IT operations sometime between 2005 and 2009	Database contains the IT outsourcing variable yearly between 2005 and 2009 for a small group of organizations	Harte Hanks
(x)	Data breach disclosures	Disclosing organization, disclosure date, state and industry of disclosing organization, and (when available) number of affected records	2,366 data breaches disclosed between 2005 and 2018	Privacy Rights Clearinghouse's Data Breach Chronology
	ite Characteristics			
(xi)	Website traffic	Alexa's ranking of top one million websites by traffic	Yearly between 2010 and 2018	Alexa
(xii)	Cloud-hosting of website	Whether an organization's server software used an IP address associated with AWS, Microsoft Azure, or Google Cloud	Snapshots of IP addresses associated with AWS, Azure, and Google taken on March 25, 2020, August 13, 2023, and August 14, 2023, respectively	Amazon, Microsoft, and Google
(xi)	Website's technology use	Website's technology use in 47 technology categories, including analytics, e- commerce, and web frameworks	Data captured between 2016 and 2018; we consider the website to have used a particular technology if we observe the usage of the technology anytime during 2016—2018	HTTP Archive

Table 2 Summary Statistics of the Analysis Sample for Prevalence

	Count	Mean	STD	Min	25%	50%	75%	Max
$severeBugReported_{it}$	4861871	0.679	0.467	0	0	1	1	1
$severeBugDisclosed_{it}$	4861871	0.599	0.490	0	0	1	1	1
$severeBugFixed_{it}$	4861871	0.571	0.495	0	0	1	1	1
$num Severe Bug Reported_{it} \\$	4861871	2.362	2.314	0	0	2	4	12
$num Severe Bug Disclosed_{it} \\$	4861871	2.177	2.366	0	0	1	4	12
$numSevereBugFixed_{it}$	4861871	2.012	2.312	0	0	1	4	12

Notes: The i subscript indexes organizations. The t subscript indexes months. $severeBugReported_{it}$, $severeBugDisclosed_{it}$, $severeBugFixed_{it}$ are binary indicator variables, each indicating whether there are severe security vulnerabilities that have been reported, disclosed, or fixed for the Apache version observed for the organization-month. $numSevereBugReported_{it}$, $numSevereBugDisclosed_{it}$, $numSevereBugFixed_{it}$ are count variables, each counting the number of severe security vulnerabilities reported, disclosed, or fixed for the Apache version observed for the organization-month. Appendix Table A1 shows the correlation between the variables.

Table 3 Summary Statistics of the Analysis Sample

	Count	Mean	STD	Min	50%	Max

Notes: All dollar amounts are in millions. All headcounts, including employment and number affected by data breaches, are in thousands of people. The yThe subscript indexes years. For public firms, we observe their characteristics at the yearly level. Appendix Table A2 shows the correlation between the variables. The rest of Table 2's notes apply.

R-squared	0.266	0.281	0.547			

Notes: We perform a log transformation for large nonnegative variables such as employment by adding one to the variable and then taking the logarithm. Standard errors are clustered at the state, industry, and month level for Columns (1), (2), (4), and (5). Standard errors are clustered at the organization and month level for Columns (3) and (6). Standard errors are shown in parentheses. *** p<0.01, ** p<0.05, * p<0.1. For regression results specific to public firms, please see Appendix Table A4.

Notes: The r subscript indexes fix releases as depicted in Figure 3. $timeToFix_{ir}$ counts the number of months it takes organization i to update their vulnerable Apache version to the fixed version r after its release. $fixed_{ir}$ is a binary indicator variable that tracks the event of interest; it is equal to 1 if the organization has updated to the fixed version, and 0 if the observation is right-censored. Appendix Table A3 shows the correlation between the variables. The rest of notes of Tables 1 and 2 apply.

Observations	92543	71343	16883	92543	92543

Notes: For stratified Cox models, stratification is performed at the organization level, and standard errors are clustered at the organization level. Clustering at the month level is not performed due to the perfect mapping between releases and the months they occurred. Public firm characteristics are not included in the regressions to avoid a significant reduction in the number of observations. The rest of the notes of Table 4 apply.

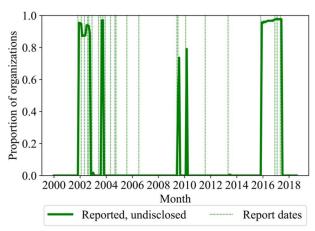

Figure 1 Proportion of Organizations with Reported Severe Security Vulnerabilities

Decompose

Notes: The fractions of organizations for a given month in Figures 1(b) and 1(c) may not perfectly sum to the fraction of organizations in Figure 1(a). This is because some organizations may have multiple reported vulnerabilities within the same month, with some being disclosed and others remaining undisclosed.

(b) Reported, undisclosed vulnerabilities

(c) Reported & disclosed vulnerabilities

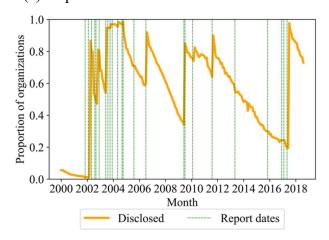

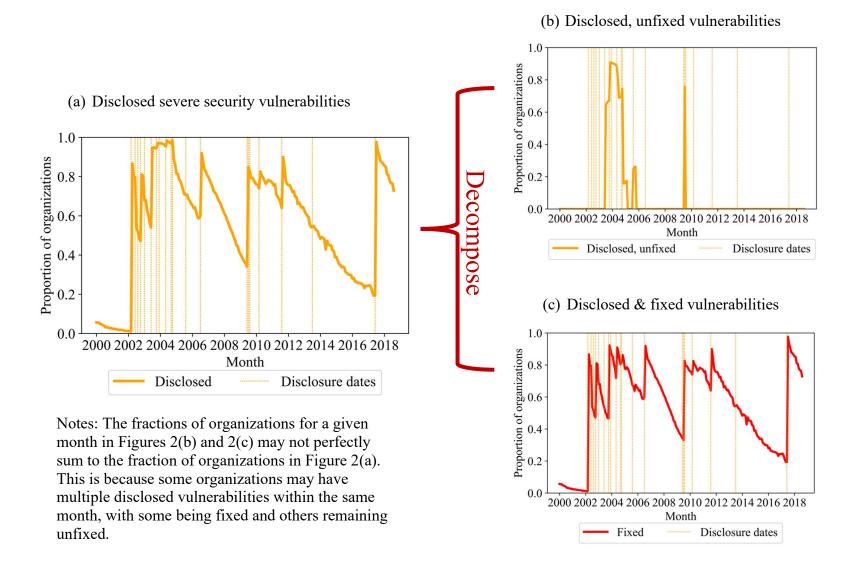

Figure 2 Proportion of Organizations with Disclosed Severe Security Vulnerabilities

Notes of Table 6 apply.

A.4. Backporting

TBD. Just a verbal argument that backporting should not undermine our results, or a more quantitative approach?
